## Slot-queue - An optimized wait-free distributed MPSC

#### 1. Motivation

A good example of a wait-free MPSC has been presented in [1]. In this paper, the authors propose a novel tree-structure and a min-timestamp scheme that allow both enqueue and dequeue to be wait-free and always complete in  $\Theta(\log n)$  where n is the number of enqueuers.

We have tried to port this algorithm to distributed context using MPI. The most problematic issue was that the original algorithm uses load-link/ store-conditional (LL/SC). To adapt to MPI, we have to propose some modification to the original algorithm to make it use only compare-and-swap (CAS). Even though the resulting algorithm pretty much preserve the original algorithm's characteristic, that is wait-freedom and time complexity of  $\Theta(\log n)$ , we have to be aware that this is  $\Theta(\log n)$ remote operations, which is very expensive. We have estimated that for an enqueue or a dequeue operation in our initial LTQueue version, there are about  $2 * \log n$  to  $10 * \log n$  remote operations, depending on data placements and the current state of the LTQueue.

Therefore, to be more suitable for distributed context, we propose a new algorithm that's inspired by LTQueue, in which both enqueue and dequeue only perform a constant number of remote operations, at the cost of dequeue having to perform  $\Theta(n)$  local operations, where n is the number of enqueuers. Because remote operations are much more expensive, this might be a worthy tradeoff.

#### 2. Structure

Each enqueue will have a local SPSC as in LTQueue [1] that supports dequeue, enqueue and readFront. There's a global queue whose entries store the minimum timestamp of the corresponding enqueuer's local SPSC.

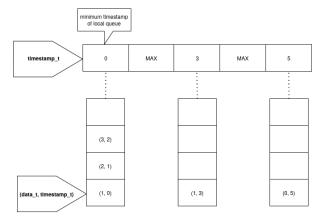

Figure 1: Basic structure of slot queue

#### 3. Pseudocode

#### 3.1. **SPSC**

The SPSC of [1] is kept in tact, except that we change it into a circular buffer implementation.

#### **Types**

```
data_t = The type of data stored
spsc_t = The type of the local SPSC
    record
    First: int
    Last: int
    Capacity: int
    Data: an array of data_t of capacity
    Capacity
    end
```

#### **Shared variables**

First: index of the first undequeued entry Last: index of the first unenqueued entry

#### Initialization

```
First = Last = 0
Set Capacity and allocate array.
```

The procedures are given as follows.

Procedure 1: spsc\_enqueue(v: data\_t) returns bool

- 1 if (Last + 1 == First)
  2 | return false
- 3 Data[Last] = v
- 4 Last = (Last + 1) % Capacity
- 5 return true

Procedure 2: spsc\_dequeue() returns data\_t

- 6 **if** (First == Last) **return**  $\perp$
- 7 res = Data[First]
- 8 First = (First + 1) % Capacity
- 9 return res

Procedure 3: spsc readFront returns data t

- 10 if (First == Last)
- 11 | return  $\perp$
- 12 return Data[First]

#### 3.2. Slot-queue

The slot-queue types and structures are given as follows:

#### **Types**

data\_t = The type of data stored
timestamp\_t = uint64\_t
spsc\_t = The type of the local SPSC

#### Shared variables

slots: An array of timestamp\_t with the number of entries equal the number of enqueuers spscs: An array of spsc\_t with the number of entries equal the number of enqueuers counter: uint64\_t

#### **Initialization**

| Initialize all local SPSCs.

Initialize slots entries to MAX.

The enqueue operations are given as follows:

Procedure 4: enqueue(rank: int, v: data\_t)
returns bool

- 1 timestamp = FAA(counter)
- 2 value = (v, timestamp)
- 3 res = spsc\_enqueue(spscs[rank], value)
- 4 if (!res) return false
- 5 if (!refreshEnqueue(rank, timestamp))
- 6 | refreshEnqueue(rank, timestamp)
- 7 return res

Procedure 5: refreshEnqueue(rank: int, ts:
timestamp\_t) returns bool

- 8 old-timestamp = slots[rank]
- 9 front = spsc readFront(spscs[rank])
- new-timestamp = front == \(\perp \) ? MAX :
  front.timestamp
- 11 if (new-timestamp != ts)
- 12 | return true
- return CAS(&slots[rank], old-timestamp,
  new-timestamp)

The dequeue operations are given as follows:

#### Procedure 6: dequeue() returns data\_t

- 14 rank = readMinimumRank()
- 15 if (rank == DUMMY || slots[rank] == MAX)
- 16 | return ⊥
- 17 res = spsc\_dequeue(spscs[rank])
- 18 **if** (res ==  $\perp$ ) **return**  $\perp$
- 19 if (!refreshDequeue(rank))
- 20 | refreshDequeue(rank)
- 21 return res

#### Procedure 7: readMinimumRank() returns int

```
22 rank = length(slots)
23 min-timestamp = MAX
24 for index in 0..length(slots)
     timestamp = slots[index]
25
     if (min-timestamp < timestamp)</pre>
26
       rank = index
2.7
28
       min-timestamp = timestamp
29 \text{ old-rank} = \text{rank}
30 for index in 0..old-rank
     timestamp = slots[index]
31
32
     \mathbf{if} (min-timestamp < timestamp)
        rank = index
33
       min-timestamp = timestamp
  return rank == length(slots) ? DUMMY :
35
   rank
```

## Procedure 8: refreshDequeue(rank: int) returns bool

36 old-timestamp = slots[rank]

# 4. Linearizability of the local SPSC

In this section, we prove that the local SPSC is linearizable.

**Lemma 4.1** (*Linearizability of spsc\_enqueue*) The linearization point of spsc\_enqueue is right after line 2 or right after line 4.

**Lemma 4.2** (*Linearizability of spsc\_dequeue*) The linearization point of spsc\_dequeue is right after line 6 or right after line 8.

**Lemma 4.3** (*Linearizability of spsc\_readFront*) The linearization point spsc\_readFront is right after line 11 or right after line 12.

**Theorem 4.4** (*Linearizability of local SPSC*) The local SPSC is linearizable.

**Proof** This directly follows from Lemma 4.1, Lemma 4.2, Lemma 4.3. □

### 5. ABA problem

Noticeably, we use no scheme to avoid ABA problem in Slot-queue. In actuality, ABA problem does not adversely affect our algorithm's correctness, except in the extreme case that the 64-bit global counter overflows, which is unlikely.

#### 5.1. ABA-safety

Not every ABA problem is unsafe. We formalize in this section which ABA problem is safe and which is not.

**Definition 5.1.1** A **CAS-sequence** on a variable v is a sequence of instructions that:

- Starts with a load  $v_0 = load(v)$ .
- Ends with a CAS (& $v_0$ ,  $v_0$ ,  $v_1$ ).

**Definition 5.1.2** A **successful CAS-sequence** on a variable v is a **CAS-sequence** on v that ends with a successful CAS.

**Definition 5.1.3** A **modification instruction** on a variable v is an atomic instruction that may change the value of v e.g. a store or a CAS.

**Definition 5.1.4** A successful modification instruction on a variable v is an atomic instruction that changes the value of v e.g. a store or a successful CAS.

**Definition 5.1.5** A **history** of successful **CAS**-sequences and **modification instructions** is a timeline of when any **CAS**-sequences start/end and when any modification instructions end.

We can define a strict partial order < on the set of **CAS-sequences** and **modification instructions** such that:

- A < B if A and B are both CAS-sequences and A ends before B starts.
- A < B if A and B are modification instructions and A ends before B ends.
- A < B if A is a modification instruction, B is a CAS-sequence and A ends before B starts.
- B < A if A is a modification instruction, B is a CAS-sequence and A ends after B ends.

**Definition 5.1.6** Consider a history of successful **CAS-sequences** and **modification instructions** on the same variable v. **ABA problem** is said to have occurred with v if there exists a **successful CAS-sequence** on v, during which there's some **successful modification instruction** on v.

**CAS-sequences** and **modification instructions** on the same variable v. A history is said to be **ABA-safe** with v if and only if:

- **ABA problem** does not occur with v in the history.
- We can reorder the successful CAS-sequences and modification instructions in the history such that:
  - ► No two successful CAS-sequences overlap with each other.
  - ► No successful modification instruction lies within another successful CAS-sequence.
  - ► The resulting history after reordering produces the same output as the original history.

## 5.2. Proof of ABA-safety

Notice that we only use CAS on:

- Line 13 of refreshEnqueue (Procedure 5), or an enqueue in general (Procedure 4).
- Line 42 of refreshDequeue (Procedure 8) or a dequeue in general (Procedure 6).

Both CAS target some slot in the slots array.

We apply some domain knowledge of our algorithm to the above formalism.

**Definition 5.2.1** A **CAS-sequence** on a slot s of an enqueue that corresponds to s is the sequence of instructions from line 8 to line 13 of its refreshEngueue.

**Definition 5.2.2** A **slot-modification instruction** on a slot s of an enqueue that corresponds to s is line 13 of refreshEnqueue.

**Definition 5.2.3** A **CAS-sequence** on a slot s of a dequeue that corresponds to s is the sequence of instructions from line 36 to line 42 of its refreshDequeue.

**Definition 5.2.4** A **slot-modification instruction** on a slot s of a dequeue that corresponds to s is line 40 or line 42 of refreshDequeue.

**Definition 5.2.5** A **CAS-sequence** of a dequeue/ enqueue is said to **observes a slot value of**  $s_0$  if it loads  $s_0$  at line 8 of refreshEnqueue or line 36 of refreshDequeue.

We can now turn to our interested problem in this section.

**Lemma 5.2.1** (Concurrent accesses on a local SPSC and a slot) Only one dequeuer and one enqueuer can concurrently modify a local SPSC and a slot in the slots array.

**Proof** This is trivial to prove based on the algorithm's definition.  $\Box$ 

**Lemma 5.2.2** (Monotonicity of local SPSC timestamps) Each local SPSC in Slot-queue contains elements with increasing timestamps.

**Proof** Each enqueue would FAA the global counter (line 1 in Procedure 4) and enqueue into the local SPSC an item with the timestamp obtained from the counter. Applying Lemma 5.2.1, we know that items are enqueued one at a time into the SPSC. Therefore, later items are enqueued by later enqueues, which obtain increasing values by FAA-ing the shared counter. The theorem holds.

**Lemma 5.2.3** A refreshEnqueue (Procedure 5) can only changes a slot to a value other than MAX.

**Proof** For refreshEnqueue to change the slot's value, the condition on line 11 must be false. Then new-timestamp must equal to ts, which is not MAX. It's obvious that the CAS on line 13 changes the slot to a value other than MAX.

**Theorem 5.2.4** (ABA safety of dequeue) Assume that the 64-bit global counter never overflows, dequeue (Procedure 6) is ABA-safe.

**Proof** Consider a **successful CAS-sequence** on slot s by a dequeue d.

Denote  $t_d$  as the value this CAS-sequence observes.

Due to Lemma 5.2.1, there can only be at most one enqueue at one point in time within d.

If there's no successful slot-modification instruction on slot s by an enqueue e within d's successful CAS-sequence, then this dequeue is ABA-safe.

Suppose the enqueue e executes the last successful slot-modification instruction on slot s within d's successful CAS-sequence. Denote  $t_e$  to be the value that e sets s.

If  $t_e \neq t_d$ , this CAS-sequence of d cannot be successful, which is a contradiction.

Therefore,  $t_e = t_d$ .

Note that e can only set s to the timestamp of the item it enqueues. That means, e must have enqueued a value with timestamp  $t_d$ . However, by definition,  $t_d$  is read before e executes the CAS. This means another process (dequeuer/enqueuer) has seen the value e enqueued and CAS s for e before  $t_d$ . By Lemma 5.2.1, this "another process" must be another dequeuer d' that precedes d.

Because d' and d cannot overlap, while e overlaps with both d' and d, e must be the *first* enqueue on s that overlaps with d. Combining with Lemma 5.2.1 and the fact that e executes the *last* successful slot-modification instruction on slot s within d's successful CAS-sequence, e must be the only enqueue that executes a successful slot-modifi-

cation instruction within d's successful CAS-sequence.

During the start of *d*'s successful CAS-sequence till the end of *e*, spsc\_readFront on the local SPSC must return the same element, because:

- There's no other dequeues running during this time
- There's no enqueue other than *e* running.
- The spsc\_enqueue of e must have completed before the start of d's successful CAS sequence, because a previous dequeuer d' can see its effect.

Therefore, if we were to move the starting time of d's successful CAS-sequence right after e has ended, we still retain the output of the program because:

- The CAS sequence only reads two shared values: slots[rank] and spsc\_readFront(), but we have proven that these two values remain the same if we were to move the starting time of *d*'s successful CAS-sequence this way.
- The CAS sequence does not modify any values except for the last CAS instruction, and the ending time of the CAS sequence is still the same.
- The CAS sequence modifies slots[rank] at the CAS but the target value is the same because inputs and shared values are the same in both cases.

We have proven that if we move *d*'s successful CAS-sequence to start after the *last* **successful slot-modification instruction** on slot s within *d*'s **successful CAS-sequence**, we still retain the program's output.

The theorem directly follows.  $\Box$ 

**Theorem 5.2.5** (ABA safety of enqueue) Assume that the 64-bit global counter never overflows, enqueue (Procedure 4) is ABA-safe.

**Proof** Consider a **successful CAS-sequence** on slot s by an enqueue e.

Denote  $t_e$  as the value this CAS-sequence observes.

Due to Lemma 5.2.1, there can only be at most one enqueue at one point in time within e.

If there's no successful slot-modification instruction on slot s by an dequeue d within e's successful CAS-sequence, then this enqueue is ABA-safe.

Suppose the dequeue d executes the last successful slot-modification instruction on slot s within e's successful CAS-sequence. Denote  $t_d$  to be the value that d sets s.

If  $t_d \neq t_e$ , this CAS-sequence of e cannot be successful, which is a contradiction.

Therefore,  $t_d = t_e$ .

If  $t_d=t_e=$  MAX, this means e observes a value of MAX before d even sets s to MAX. If this MAX value is the initialized value of s, it's a contradiction, as s must be non-MAX at some point for a dequeue such as d to run. If this MAX value is set by an enqueue, it's also a contradiction, as refreshEnqueue cannot set a slot to MAX. Therefore, this MAX value is set by a dequeue d'. If  $d'\not\equiv d$  then it's a contradiction, because between d' and d, s must be set to be a non-MAX value before d can be run. Therefore,  $d'\equiv d$ . But, this means e observes a value set by d, which violates our assumption.

Therefore  $t_d=t_e=t'\neq \text{MAX}$ . e cannot observe the value t' set by d due to our assumption. Suppose e observes the value t' from s set by another enqueue/dequeue call other than d.

If this "another call" is a dequeue d' other than d, d' precedes d. By Lemma 5.2.2, after each dequeue, the front element's timestamp will be increasing, therefore, d' must have set s to a timestamp smaller than  $t_d$ . However, e observes  $t_e = t_d$ . This is a contradiction.

Therefore, this "another call" is an enqueue e' other than e, e' precedes e. We know that an enqueue only sets s to the timestamp it obtains. If e' does not overlap with d, then after e' has ended, the local SPSC is either empty or has the item e' enqueues as the front element. Therefore, when d

runs, it dequeues out the item e' enqueues and set s to  $t_d$  which is greater than the timestamp of the item e' enqueues. Therefore, e' overlaps with d.

For e' to set s to the same value as d, e''s spsc\_readFront must serialize after d's spsc\_dequeue.

Because e' and e cannot overlap, while d overlaps with both e' and e, d must be the *first* dequeue on s that overlaps with e. Combining with Lemma 5.2.1 and the fact that d executes the *last* successful slot-modification instruction on slot s within e's successful CAS-sequence, d must be the only dequeue that executes a successful slot-modification instruction within e's successful CAS-sequence.

During the start of e's successful CAS-sequence till the end of d, spsc\_readFront on the local SPSC must return the same element, because:

- There's no other enqueues running during this time.
- There's no dequeue other than *d* running.
- The spsc\_dequeue of d must have completed before the start of e's successful CAS sequence, because a previous enqueuer e' can see its effect.

Therefore, if we were to move the starting time of e's successful CAS-sequence right after d has ended, we still retain the output of the program because:

- The CAS sequence only reads two shared values: slots[rank] and spsc\_readFront(), but we have proven that these two values remain the same if we were to move the starting time of e's successful CAS-sequence this way.
- The CAS sequence does not modify any values except for the last CAS/store instruction, and the ending time of the CAS sequence is still the same.
- The CAS sequence modifies slots[rank] at the CAS but the target value is the same because inputs and shared values are the same in both cases.

We have proven that if we move $e$ 's successful
CAS-sequence to start after the last successful
slot-modification instruction on slot s within
e's successful CAS-sequence, we still retain the
program's output.

The theorem directly follows.  $\Box$ 

**Theorem 5.2.6** (*ABA safety*) Assume that the 64-bit global counter never overflows, Slot-queue is ABA-safe.

**Proof** This follows from Theorem 5.2.5 and Theorem 5.2.4.  $\Box$ 

## 6. Linearizability of Slot-queue

We will prove the linearizability of Slot-queue by pointing out the linearization points of enqueue (Procedure 4) and dequeue (Procedure 6).

**Lemma 6.1** (*Linearizability of enqueue*) The linearization point of enqueue is right after .

**Lemma 6.2** (*Linearizability of dequeue*) The linearization point of dequeue is right after .

**Theorem 6.3** (*Linearizability of Slot-queue*) The local SPSC is linearizable.

#### 7. Wait-freedom

The algorithm is trivially wait-free as there is no possibility of infinite loops.

## 8. Memory-safety

The algorithm is memory-safe: No memory deallocation happens and accesses are only made on allocated memory.
